The Hyacinth Macaw (*Anodorhynchus hyacinthinus*) is an endangered parrot. A population in the Pantanal (Brazil) has been monitored by Neiva M.R. Guedes for six years. We applied DNA fingerprinting on 56 chicks born over four reproductive seasons. Some bands detected by the minisatellite probe 33.6 were present in all chicks and may constitute markers for this population, which is important for reintroduction purposes. When these bands are included in the analysis, the mean similarity index (SI) among unrelated birds is 0.40, but when they are excluded, it is 0.28, close to the value found with probe 33.15. Female linked bands detected by probe 33.15 allowed for the determination of a sex ratio of 1:1 among the nestlings. The SI among chicks of the same nest is higher

than between chicks of different nests, suggesting that the former birds are more closely interrelated, possibly siblings. The SI among chicks before to close nests is similar to the one among chicks from nests farther away. These results support field observations that Hyacinth Macaws are monogamous and probably do not have extra-pair fertilisation.
